5-Bit Programmable Synchronous Switching Regulator Controller for Pentium® II Processor

**ADP3011**

**FEATURES**
- 5-Bit Digitally Programmable 1.8 V to 3.5 V Output Voltage
- Dual N-Channel Synchronous Driver
- High Efficiency
- Current-Mode Operation
- Short Circuit Protection
- Power Good Output
- Integrated Overvoltage Protection Crowbar
- 16-Lead SOIC Package
- VRM 8.2 Compatible

**APPLICATIONS**
- Desktop PC Power Supply for:
  - Pentium II Processor
  - Pentium Pro Processor
  - Pentium Processor
  - AMD–K6 Processor
  - VRM Modules

**GENERAL DESCRIPTION**

The ADP3011 is a highly efficient synchronous switching regulator controller optimized for Pentium II Processor applications where 5 V is stepped down to a digitally controlled output voltage between 1.8 V and 3.5 V. Using a 5-bit DAC to read a voltage identification (VID) code directly from the processor, the ADP3011 uses a current-mode constant off-time architecture to generate its precise output voltage.

The ADP3011 drives two synchronous N-channel MOSFETS at a switching frequency of 250 kHz. The constant off-time architecture maintains constant inductor ripple current while current-mode operation provides excellent line and load transient response. The operating current level is user programmable via an external current sense resistor.

## CAUTION

ESD (electrostatic discharge) sensitive device. Electrostatic charges as high as 4000 V readily accumulate on the human body and test equipment and can discharge without detection. Although the ADP3011 features proprietary ESD protection circuitry, permanent damage may occur on devices subjected to high energy electrostatic discharges. Therefore, proper ESD precautions are recommended to avoid performance degradation or loss of functionality.

APPLICATION INFORMATION
The ADP3011 uses a current-mode, constant-off-time control technique to switch a pair of external N-channel MOSFETs in a synchronous rectified buck converter application. Due to the constant-off-time operation, no slope compensation is needed. A unique feature of the constant-off-time control technique is that the converter’s frequency becomes a function of the ratio of input voltage to output voltage. The off time is determined by the value of the external capacitor connected to the C_T pin. The on time varies in such a way that a regulated output voltage is maintained.

The output voltage is sensed by an internal voltage divider that is connected to the SENSE– pin. A voltage-error amplifier g_m compares the values of the divided output voltage with a reference voltage. The reference voltage is set by an onboard 5-bit DAC, which reads the code present at the voltage identification (VID) pins and converts it to a precise value between 600 mV and 1.167 V. Refer to Table I for the output voltage vs. VID pin code information.

During continuous-inductor-current mode of operation, the voltage-error amplifier g_m and the current comparator CMPI are the main control elements. During the on time of the high side MOSFET, the current comparator CMPI monitors the voltage between the SENSE+ and SENSE– pins. When the voltage level between the two pins reaches the threshold level V_T1, the high side drive output is switched to zero, which turns off the high side MOSFET. The timing capacitor C_T is now discharged at a rate determined by the off time controller. In order to maintain a ripple current in the inductor, which is independent of the output voltage, the discharge current is made proportional to the value of the output voltage (measured at the SENSE– pin). While the timing capacitor is discharging, the low side drive output goes high, turning on the low side MOSFET. When the voltage level on the timing capacitor has discharged to the threshold voltage level V_T2, comparator CMPT resets the SR flip-flop. The output of the flip-flop forces the low side drive output to go low and the high side drive output to go high. As a result, the low side switch is turned off and the high side switch is turned on. The sequence is then repeated. As the load current increases, the output voltage starts to decrease. This causes an increase in the output of the voltage-error amplifier, which, in turn, leads to an increase in the current comparator threshold V_T1, thus tracking the load current.

To prevent cross conduction of the external MOSFETs, feedback is incorporated to sense the state of the driver output pins. Before the low side drive output can go high, the high side drive output must be low. Likewise, the high side drive output is unable to go high while the low side drive output is high.

#### Power Good

The ADP3011 has an internal monitor which monitors the output voltage and drives the PWRGD pin of the device. This pin is an open drain output whose high level (when connected to a pull-up resistor) indicates that the output voltage has been within a ±5% regulation band of the targeted value for more than 500 µs. The PWRGD pin will go low if the output is outside the regulation band for more than 500 µs.

#### Output Crowbar

An added feature of using an N-channel MOSFET as the synchronous switch is the ability to crowbar the output with the same MOSFET. If the output voltage is 15% greater than the desired regulated value, the ADP3011 will turn on the lower MOSFET, which will current-limit the source power supply or blow its fuse, pull down the output voltage, and thus save the expensive microprocessor from destruction. The crowbar function releases at approximately 50% of the nominal output voltage. For example, if the output is programmed to 2.0 V, but is pulled up to 2.3 V or above, the crowbar will turn on the lower MOSFET. If in this case the output is pulled down to less than 1.0 V, the crowbar will release, allowing the output voltage to recover to 2.0 V.
Shutdown
The ADP3011 has a shutdown pin that is pulled logic low by an internal resistor. The device functions normally in this condition. This pin should be pulled high externally to disable the output drives.

Calculation of Component Values
The design parameters for a typical 300 MHz Pentium II application (Figure 2) are as follows:

- Input voltage: $V_{IN} = 5$ V
- Auxiliary input: $V_{CC} = 12$ V
- Output voltage: $V_O = 2.8$ V

Maximum output current:
$I_{OMAX} = 14.2$ Adc

Minimum output current:
$I_{OMIN} = 0.8$ Adc

Static tolerance of the supply voltage for the processor core:
$\Delta V_{OST+} = 100$ mV
$\Delta V_{OST-} = -60$ mV

Transient tolerance (for less than 2 ms) of the supply voltage for the processor core when the load changes between the minimum and maximum values with a di/dt of 30 A/μs:
$\Delta V_{OTR+} = 130$ mV
$\Delta V_{OTR-} = -130$ mV

Input current di/dt when the load changes between the minimum and maximum values: less than 0.1 A/μs

The above requirements correspond to Intel’s published power supply requirements based on VRM 8.2 guidelines.

$C_T$ Selection for Operating Frequency
The ADP3011 uses a constant-off-time architecture with $t_{OFF}$ determined by an external timing capacitor $C_T$. Each time the high side N-channel MOSFET switch turns on, the voltage across $C_T$ is reset to approximately 3.3 V. During the off time, $C_T$ is discharged by a constant current of 65 μA to 2.3 V, that is by 1 V. The value of the off time is calculated from the preferred continuous-mode operating frequency. Assuming a nominal operating frequency of $f_{NOM} = 200$ kHz at an output voltage of $V_O = 2.8$ V, the corresponding off time is:

$$t_{OFF} = \left(1 - \frac{V_O}{V_{IN}}\right) \frac{1}{f_{NOM}} = 2.2 \mu s$$

The timing capacitor can be calculated from the equation:

$$C_T = \frac{t_{OFF} \times 65 \mu A}{1V} = 143 \text{ pF}$$

The converter operates at the nominal operating frequency only at the above specified $V_O$ and at light load. At higher $V_O$, and heavy load, the operating frequency decreases due to the parasitic voltage drops across the power devices. The actual minimum frequency at $V_O = 2.8$ V is calculated to be 160 kHz (see Equation 1 below). Where

- $I_{IN}$ is the input dc current (assuming an efficiency of 90%, $I_{IN} = 9$ A)
- $R_{IN}$ is the resistance of the input filter (estimated value: 7 mΩ)
- $R_{DS(ON)HSF}$ is the resistance of the high side MOSFET (estimated value: 10 mΩ)
- $R_{DS(ON)LSF}$ is the resistance of the low side MOSFET (estimated value: 10 mΩ)
- $R_{SENSE}$ is the resistance of the sense resistor (estimated value: 7 mΩ)
- $R_L$ is the resistance of the inductor (estimated value: 6 mΩ)

$C_O$ Selection—Determining the ESR
The selection of the output capacitor is driven by the required ESR and capacitance $C_O$. The ESR must be small enough that both the resistive voltage deviation due to a step change in the load current and the output ripple voltage stay below the values defined in the specification of the supplied microprocessor. The capacitance, $C_O$, must be large enough that the output is held up while the inductor current ramps up or down to the value corresponding to the new load current.

The total static tolerance of the Pentium II processor is 160 mV. Taking into account the ±1% setpoint accuracy of the ADP3011, and assuming a 0.5% (or 14 mV) peak-to-peak ripple, the allowed static voltage deviation of the output voltage when the load changes between the minimum and maximum values is 0.08 V. Assuming a step change of $\Delta I = I_{OMAX} - I_{OMIN} = 13.4$ A, and allocating all of the total allowed static deviation to the contribution of the ESR sets the following limit:

$$R_{H(\text{MAX})} = ESR_{MAX} = \frac{0.08}{13.4} = 0.6 \text{ mΩ}$$

The output filter capacitor must have an ESR of less than 5.9 mΩ. One can use, for example, six FA type capacitors from Panasonic, with 2700 μF capacitance, 10 V voltage rating, and 34 mΩ ESR. The six capacitors have a total typical ESR of ~ 5 mΩ when connected in parallel.

$$f_{MIN} = \frac{1}{t_{OFF}} \times \frac{V_{IN} - I_{IN}R_{IN} - I_{OMAX} (R_{DS(ON)HSF} + R_{SENSE} + R_L) - V_O}{V_{IN} - I_{IN}R_{IN} - I_{OMAX} (R_{DS(ON)HSF} + R_{SENSE} + R_L - R_{DS(ON)LSF})} = 160 \text{ kHz}$$

(1)
Inductor Selection

The minimum inductor value can be calculated from ESR, off time, dc output voltage and allowed peak-to-peak ripple voltage.

\[
L_{MIN} = \frac{V_{OFF} R_{ESR}}{V_{RIPPLE}} = \frac{2.8 \times 2.2 \times 5.9 m}{14 m} = 2.6 \mu H
\]

The minimum inductance gives a peak-to-peak ripple current of 2.15 A, or 15% of the maximum dc output current \(I_{OMAX}\).

The inductor peak current in normal operation is:

\[
I_{LPEAK} = I_{OMAX} + \frac{IRPP}{2} = 15.3 A
\]

The inductor valley current is:

\[
I_{LYALLEY} = I_{LPEAK} - IRPP = 13 A
\]

The requirements for selecting an inductor should have an inductance of 2.6 \(\mu H\) at full load current and should not saturate at the worst-case overload or short circuit current at the maximum specified ambient temperature. A suitable inductor is the CTX12-13855 from Coiltronics, which is 4.4 \(\mu H\) at 1 A and about 2.5 \(\mu H\) at 14.2 A.

Tips for Selecting Inductor Core

Ferrite designs have very low core loss, so the design should focus on copper loss and on preventing saturation. Molypermalloy, or MPP, is a low loss core material for toroids, which yields the smallest size inductor, but MPP cores are more expensive than ferrite cores or the Kool Mu™ cores from Magnetics, Inc. The lowest cost core is made of powdered iron, for example the #52 material from Micrometals, Inc., but yields the largest size inductor.

\(C_0\) Selection—Determining the Capacitance

The minimum capacitance of the output capacitor is determined from the requirement that the output be held up while the inductor current ramps up (or down) to the new value. The minimum capacitance should produce an initial \(dv/dt\) which is equal (but opposite in sign) to the \(dv/dt\) obtained by multiplying the \(di/dt\) in the inductor and the ESR of the capacitor.

\[
C_{MIN} = \frac{I_{OMAX} - I_{OMIN}}{R_{ESR} (di/dt)} = \frac{14.2 - 0.8}{5.9 m (2.2 / 4.4 \mu H)} = 4.5 mF
\]

In the above equation the value of \(di/dt\) is calculated as the smaller voltage across the inductor (i.e., \(V_{IN-V_O}\) rather than \(V_O\)) divided by the maximum inductance (4.4 \(\mu H\)) of the CTX12-13855 inductor from Coiltronics. The parallel-connected six 2700 \(\mu F/10 V\) FA series capacitors from Panasonic have a total capacitance of 16,200 \(\mu F\), so the minimum capacitance requirement is met with ample margin.

\(R_{SENSE}\)

The value of \(R_{SENSE}\) is based on the required output current. The current comparator of the ADP3011 has a threshold range that extends from 0 mV to 125 mV (minimum). Note that the full 125 mV range cannot be used for the maximum specified nominal current, as headroom is needed for current ripple, transients and inductor core saturation.

The current comparator threshold sets the peak of the inductor current yielding a maximum output current \(I_{OMAX}\), which equals the peak value less half of the peak-to-peak ripple current. Solving for \(R_{SENSE}\) and allowing a margin for tolerances inside the ADP3011 and in the external component values yields:

\[
R_{SENSE} = \frac{(125 mV/[1.2(I_{OMAX} + IRPP/2)])}{6.8 m\Omega}
\]

A practical solution is to use three 20 mΩ resistors in parallel, with an effective resistance of about 6.7 mΩ.

Once \(R_{SENSE}\) has been chosen, the peak short-circuit current \(I_{SC(PK)}\) can be predicted from the following equation:

\[
I_{SC(PK)} = \frac{(145 mV)/R_{SENSE} = (145 mV)/(6.7 m\Omega) = 21.5 A}
\]

The actual short-circuit current is less than the above calculated \(I_{SC(PK)}\) value because the off time rapidly increases when the output voltage drops below 1 V. The relationship between the off time and the output voltage is:

\[
t_{OFF} \approx \frac{C_f \times 1V}{V_o} + 2 \mu A
\]

With a short across the output, the off time will be about 70 \(\mu s\). During that off time the inductor current gradually decays. The amount of decay depends on the \(L/R\) time constant in the output circuit. With an inductance of 2.5 \(\mu H\) and total resistance of 23 \(\Omega\), the time constant will be 10 \(\mu s\), which yields a valley current of 11.3 A and an average short-circuit current of about 16.3 A. To safely carry the short-circuit current, the sense resistor must have a power rating of at least 16.3 A\(^2\) \times 6.8 mΩ = 1.8 W.

Current Transformer Option

An alternative to using low value and high power current sense resistors is to reduce the sensed current by using a low cost current transformer and a diode. The current can then be sensed with a small-size, low cost SMT resistor. If we use a transformer with one primary and 50 secondary turns, the worst-case resistor dissipation is reduced to a fraction of a mW. Another advantage of using this option is the separation of the current and voltage sensing, which makes the voltage sensing more accurate.

Power MOSFET

Two external N-channel power MOSFETs must be selected for use with the ADP3011, one for the main switch, and an identical one for the synchronous switch. The main selection parameters for the power MOSFETs are the threshold voltage \(V_{GS(TH)}\) and the on resistance \(R_{DS(ON)}\).

The minimum input voltage dictates whether standard threshold or logic-level threshold MOSFETs must be used. For \(V_{IN}>8 V\), standard threshold MOSFETs (\(V_{GS(TH)} < 4 V\)) may be used. If \(V_{IN}\) is expected to drop below 8 V, logic-level threshold MOSFETs (\(V_{GS(TH)} < 2.5 V\)) are strongly recommended. Only logic-level MOSFETs with \(V_{GS}\) ratings higher than the absolute maximum of \(V_{CC}\) should be used.
The maximum output current $I_{OMAX}$ determines the $R_{DS(ON)}$ requirement for the two power MOSFETs. When the ADP3011 is operating in continuous mode, the simplifying assumption can be made that one of the two MOSFETs is always conducting the average load current.

For $V_{IN} = 5$ V and $V_O = 2.8$ V, the maximum duty ratio of the high side FET is:

$$D_{MAXH} = (1 - f_{MIN} \times t_{OFF}) = (1 - 160 \text{ kHz} \times 2.2 \mu s) = 65\%$$

The maximum duty ratio of the low side (synchronous rectifier) FET is:

$$D_{MAXL} = 1 - D_{MAXH} = 35\%$$

The maximum rms current of the high side FET is:

$$I_{RMSH} = [D_{MAXH}(I_{LVALLEY}^2 + I_{IPeak}^2 + I_{LVALLEY}I_{LPeak})/3]^{0.5} = 11.5 \text{ Arms}$$

The maximum rms current of the low side FET is:

$$I_{RMSL} = [D_{MAXL}(I_{LVALLEY}^2 + I_{IPeak}^2 + I_{LVALLEY}I_{LPeak})/3]^{0.5} = 8.41 \text{ Arms}$$

The $R_{DS(ON)}$ for each FET can be derived from the allowable dissipation. If we allow 5% of the maximum output power for FET dissipation, the total dissipation will be:

$$P_{ETALL} = 0.05 \times V_O I_{OMAX} = 2 \text{ W}$$

Allocating two-thirds of the total dissipation for the high side FET and one-third for the low side FET, the required minimum FET resistances will be:

$$R_{DS(ON)HS(MIN)} = 1.33/11.5^2 = 10 \text{ m}\Omega$$

$$R_{DS(ON)LSP(MIN)} = 0.67/8.41^2 = 9.5 \text{ m}\Omega$$

Note that there is a tradeoff between converter efficiency and cost. Larger FETs reduce the conduction losses and allow higher efficiency but lead to increased cost. If efficiency is not a major concern the Fairchild MOSFET NDP6030L or International Rectifier IRL3103 is an economical choice for both the high side and low side positions. Those devices have an $R_{DS(ON)}$ of 14 m$\Omega$ at $V_{GS} = 10$ V and at 25°C. The low side FET is turned on with at least 10 V. The high side FET, however, is turned on with only 12 V – 5 V = 7 V. If we check the typical output characteristics of the device in the data sheet, we find that for an output current of 10 A, and at a $V_{GS}$ of 7 V, the $V_{DS}$ is 0.15 V, which gives a $R_{DS(ON)} = V_{DS}/I_D = 15$ m$\Omega$. This value is only slightly above the one specified at a $V_{GS}$ of 10 V, so the resistance increase due to the reduced gate drive can be neglected. We have to modify, however, the specified $R_{DS(ON)}$ at the expected highest FET junction temperature of 140°C by a $R_{DS(ON)MULT}$ multiplier, using the graph in the data sheet. In our case:

$$R_{DS(ON)MULT} = 1.7$$

Using this multiplier, the expected $R_{DS(ON)}$ at 140°C is 1.7 x 14 = 24 m$\Omega$.

The high side FET dissipation is:

$$P_{DFETH} = I_{RMSH}^2 R_{DS(ON)} + 0.5 V_{IN} I_{IPeak} Q_g I_{MAX} I_G = 3.72 \text{ W}$$

where the second term represents the turn-off loss of the FET. (In the second term, $Q_g$ is the gate charge to be removed from the gate for turn-off and $I_G$ is the gate current. From the data sheet, $Q_g$ is about 50 nC –70 nC and the gate drive current provided by the ADP3011 is about 1 A.)

The low side FET dissipation is:

$$P_{DFETL} = I_{RMSL}^2 R_{DS(ON)} = 1.7 \text{ W}$$

(Note that there are no switching losses in the low side FET.)

To remove the dissipation of the chosen FETs, proper heatsinks should be used. The Thermalloy 6030 heatsink has a thermal impedance of 13°C/W with convection cooling. With this heatsink, the junction-to-ambient thermal impedance of the chosen high side FET $\theta_{JAH}$ will be 13 (heatsink-to-ambient) + 2 (junction-to-case) + 0.5 (case-to-heatsink) = 15.5°C/W.

At full load and at 50°C ambient temperature, the junction temperature of the high side FET is:

$$T_{JHSAX} = T_A + \theta_{JAH} P_{DFETH} = 105°C$$

A smaller heatsink may be used for the low side FET, e.g., the Thermalloy type 7141 (0 = 20.3°C/W). With this heatsink, the thermal impedance $\theta_{JALS}$ for the low side FET = 33.8°C/W.

The low side FET junction temperature is:

$$T_{JLSAX} = T_A + \theta_{JALS} P_{DFETL} = 106°C$$

All of the above calculated junction temperatures are safely below the 175°C maximum specified junction temperature of the selected FET.

The maximum operating junction temperature of the ADP3011 is calculated as follows:

$$T_{JCMAX} = T_A + \theta_{JA} (I_{CC} V_{CC} + P_{DR})$$

where $\theta_{JA}$ is the junction to ambient thermal impedance of the ADP3011 and $P_{DR}$ is the drive power. From the data sheet, $\theta_{JA}$ is equal to 110°C/W and $I_{CC}$ = 2.7 mA. $P_{DR}$ can be calculated as follows:

$$P_{DR} = (C_{RSS} + C_{ISS}) V_{CC}^2 f_{MAX} = 307 \text{ mW}$$

The result is:

$$T_{JCMAX} = 86°C$$

$C_{IN}$ Selection and Input Current di/dt Reduction

In continuous-inductor-current mode, the source current of the high side MOSFET is a square wave with a duty ratio of $V_O/ V_{IN}$. To keep the input ripple voltage at a low value, one or more capacitors with low equivalent series resistance (ESR) and adequate ripple-current rating must be connected across the input terminals. The maximum rms current of the input bypass capacitors is:

$$I_{CRMS} = [V_O(V_{IN} - V_O)]^{0.5} I_{OMAX} /V_{IN} = 7 \text{ Arms}$$
Let us select the FA-type capacitor with 2700 µF capacitance and 10 V voltage rating. The ESR of that capacitor is 34 mΩ and the allowed ripple current at 100 kHz is 1.94 A. At 105°C we would need to connect at least four such capacitors in parallel to handle the calculated ripple current. At 50°C ambient, however, the ripple current can be increased, so three capacitors in parallel are adequate.

The ripple voltage across the three paralleled capacitors is:

$$V_{\text{INRPL}} = I_{\text{OMAX}} \left[ \text{ESR}_I^3 + D_{\text{MAX}} f/(3 C_{\text{IN}} f_{\text{MIN}}) \right] = 140 \text{ mV } p-p$$

To further reduce the effect of the ripple voltage on the system supply voltage bus and to reduce the input-current di/dt to below the recommended maximum of 0.1 A/µs, an additional small inductor (L > 1.7 µH @ 10 A) should be inserted between the converter and the supply bus (see Figure 2).

**Feedback Loop Compensation Design**

To keep the peak-to-peak output voltage deviation as small as possible, the low frequency output impedance (i.e., the output resistance) of the converter should be made equal to the ESR of the output capacitor. That can be achieved by having a single-pole roll-off of the voltage gain of the $g_m$ error amplifier, where the pole frequency coincides with the ESR zero of the output capacitor. A gain with single-pole roll-off requires that the $g_m$ amplifier is terminated by the parallel combination of a resistor and capacitor. The required resistor value can be calculated from the equation:

$$\frac{36 \times R_{\text{SENSE}}}{g_m \left( 145 \text{ kΩ} | R_{\text{COMP}} \right)} = R_E$$

where $g_m = 2.2 \text{ ms}$ and the quantities 36 and 145 kΩ are characteristic of the ADP3011. The calculated compensating resistance is:

$$R_1 \parallel R_2 = R_{\text{COMP}} = 31 \text{ kΩ}$$

The compensating capacitance is determined from the equality of the pole frequency of the error amplifier gain and the zero frequency of the impedance of the output capacitor.

$$C_{\text{COMP}} = \frac{R_E C_{\text{OUT}}}{R_{\text{COMP}}} = \frac{5 \times 16.2 \text{ mF}}{31 \text{ kΩ}} = 2.6 \text{ nF}$$

In the application circuit we tested, we found that the compensation scheme shown in Figure 2 gave the optimal response to meet the Pentium II dc/dc static and transient specifications with sufficient margins including the ADP3011’s initial error tolerance, the PCB layout trace resistances, and the external component parasitics. If we increase the load resistance to the COMP pin, the static regulation will improve. The load transient response, however, will get worse. In Figure 2, if we decrease the $R_1 = 150 \text{ kΩ}$ resistor vs. the $R_2 = 39 \text{ kΩ}$ resistor, the regulation band will shift positive in relation to the 2.8 V. If we increase the $R_1$ resistor, the regulation band will shift negative. It may be necessary to adjust these resistor values to obtain the best static and dynamic regulation compliance depending on the output capacitor ESR and the parasitic trace resistances of the PCB layout.
BOARD LAYOUT
A multilayer PCB is recommended with a minimum of two copper layers. One layer on top should be used for traces interconnecting low power SMT components. The ground terminals of those components should be connected with vias to the bottom traces connecting directly to the ADP3011 ground pins. One layer should be a power ground plane. If four layers are possible, one additional layer should be an internal system ground plane, and one additional layer can be used for other system interconnections.

When laying out the printed circuit board, the following checklist should be used to ensure proper operation of the ADP3011. It is advisable to follow the evaluation board layout as closely as possible. If necessary, contact Analog Devices Application Engineering for layout suggestions.

Board Layout Guidelines
1. The power loop should be routed on the PCB to encompass small areas to minimize radiated switching noise energy to the control circuit and thus to avoid circuit problems caused by noise. This technique also helps to reduce radiated EMI. The power loop includes the input capacitors, the two MOSFETs, the sense resistor, the inductor, and the output capacitors. The ground terminals of the input capacitors, the low side FET, the ADP3011, and the output capacitors should be connected together with short and wide traces. It is best to use an internal ground plane.

2. The PGND (power ground) pin of the ADP3011 must return to the grounded terminals of the input and output capacitors and to the source of the low side MOSFET with the shortest and widest traces possible. The AGND (analog ground) pin has to be connected to the ground terminals of the timing capacitor and the compensating capacitor, again with the shortest leads possible, and before it is connected to the PGND pin.

3. The positive terminal of the input capacitors must be connected to the drain of the high side MOSFET. The source terminal of this FET is connected to the drain of the low side FET, (whose source is connected to the ground plane direct) with the widest and shortest traces possible. To kill parasitic ringing at the input of the buck inductor due to parasitic capacitances and inductances, a small (L > 3 mm) ferrite bead is recommended to be placed in the drain lead of the low side FET. Also, to minimize dissipation of the high side FET, a low voltage 1 A Schottky diode can be connected between the input of the buck inductor and the source of the low side FET.

4. The positive terminal of the bypass capacitors of the +12 V supply must be connected to the VIN pin of the ADP3011 with the shortest leads possible. The negative terminals must be connected to the PGND pin of the ADP3011.

5. The sense pins of the ADP3011 must be connected to the sense resistor with as short traces as possible. Make sure that the two sense traces are routed together with minimum separation (<1 mm). The output side of the sense resistor should be connected to the VCC pin(s) of the CPU with as short and wide PCB traces as possible to reduce the VCC voltage drop. (Each square unit of 1 ounce Cu-trace has a resistance of ~0.53 mΩ. At 14 A, each mΩ of PCB trace resistance between current sense resistor output and VCC terminal(s) of the CPU will reduce the regulated output voltage by 14 mV. The filter capacitors to ground at the sense terminals of the IC should be as close as possible (<8 mm) to the ADP3011. The common ground of the optional filter capacitors should be connected to the AGND pin of the ADP3011 with the shortest traces possible (<10 mm).

6. The microprocessor load should be connected to the output terminals of the converter with the widest and shortest traces possible. Use overlapping traces in different layers to minimize interconnection inductance.
